## FOREWORD

The research reported herein was sponsored by the Arnold Engineering Development Center (AEDC), Air Force Systems Command (AFSC), under Program Element 6540223F and is related to Project 8953, Task 895309.

The results of research presented in this report were obtained by ARO, Inc. (a subsidiary of Sverdrup & Parcel and Associates, Inc.), contract operator of the AEDC, AFSC, Arnold Air Force Station, Tennessee, under Contract F40600-69-C-0001. The work was performed from March 1965 to June 1967 under ARO Projects No. PW5728 and PW3517, and the manuscript was submitted for publication on April 18, 1968.

This technical report has been reviewed and is approved.

**ABSTRACT**

An experimental and theoretical investigation was conducted to determine the degree of jet boundary simulation obtainable for under-expanded jets exhausting into a quiescent atmosphere. Tests were conducted with nitrogen, carbon dioxide, and helium gases, and theoretical boundaries were obtained by a method-of-characteristics solution. It was determined that the method-of-characteristics solution accurately represents the experimental jet boundaries and that the matching of the parameters  $\delta_j$  and  $M_1/\gamma$  gives good boundary simulation for a wide range of jet conditions. Also a rapid, simple method for estimating jet boundary shape is developed from the method-of-characteristics results.

$A_S/A^*$	Nozzle spherical area ratio, $\frac{2}{1 + \cos \theta_N} \left( \frac{d_e}{d^*} \right)^2$
$d_e$	Nozzle exit diameter
$d^*$	Nozzle throat diameter
$\ell_j$	Distance along the nozzle wall measured from the throat to the nozzle exit
$\ell_1$	Distance measured from the nozzle exit along the inviscid jet boundary
$M$	Mach number
$n$	Distance measured normal to the inviscid jet boundary, positive outside the inviscid jet
$p$	Pressure
$p_p$	Pressure measured by the traversing probe

## SECTION I INTRODUCTION

In recent years, much interest has arisen in the structure and properties of highly underexpanded rocket or ramjet exhaust plumes. This interest has been created by problems such as heating and erosion of adjacent surfaces, radar and communication signal interference, separation of flow over the vehicle, and radiation emitted by the large exhaust plumes. Studies of and attempts to obtain solutions to these problems have led to the construction of high altitude test facilities and the adaptation of some existing facilities. Methods used for the experimental simulation of the full-scale jets vary in complexity from the use of small cold-gas jets to an almost exact duplication of the full-scale jets. The degree of similitude required and/or used depends on the particular problem under investigation and is discussed in Ref. 1. However the tremendous vacuum pumping capacities required and the complexity and cost of hot rocket tests frequently dictate that studies be conducted with small jets of cold gases.

One jet characteristic frequently desired is that the boundary of the experimental jet duplicates that of the full-scale jet. In an early study, Love (Ref. 2) concluded that for slightly underexpanded jets ( $p_j/p_\infty$  from 1 to 10) good boundary simulation was obtained if the initial angle,  $\delta_j$ , of the jet boundary was matched. Goethert (Ref. 3) later proposed matching the parameters  $\delta_j$  and  $\gamma M_j^2/\beta_j$  for highly underexpanded jets. Pindzola (Ref. 4) concluded that better simulation could be obtained by matching  $\delta_j$  and  $\gamma M_1^2/\beta_1$  where the Mach number is now based on the jet boundary conditions rather than the nozzle exit conditions as proposed by Goethert.

The objective of the investigation reported herein was to determine the degree of jet boundary simulation obtained using Pindzola's parameters and to determine if other simulation parameters might prove more useful. The investigation included both experimental and theoretical studies of the jet boundaries. Values of the simulation parameters  $\delta_j$  and  $\gamma M_1^2/\beta_1$  were selected that were representative of underexpanded jet plumes, and tests were conducted with nitrogen ( $N_2$ ), helium (He), and carbon dioxide ( $CO_2$ ) jets at constant values of the parameters. In addition, jet boundaries were calculated for several sets of simulation parameters by an approximate method and also by a method-of-characteristics solution.

From these studies it was determined that although the parameters  $\delta_j$  and  $\gamma M_1^2/\beta_1$  gave good jet boundary duplication, better duplication

could be obtained by matching the parameters  $\delta_j$  and  $M_1/\gamma$ . Also, a simple method was developed for rapidly predicting the jet boundary for a wide range of conditions.

## SECTION II THEORETICAL BOUNDARY CALCULATIONS

### 2.1 LATVALA'S APPROXIMATION

The approximation used by Pindzola (Ref. 4) for the original evaluation of the simulation parameters  $\delta_j$  and  $\gamma M_1^2/\beta_1$  was developed by Latvala in Ref. 5. Latvala's approximation is based on quasi-one-dimensional relations and the assumption of isentropic, radial flow from the nozzle. It is an adaptation of a method presented by Adamson and Nichols in Ref. 6, but uses a spherical rather than a planar area to define the flow area of the jet.

The approximate solution starts with the known initial angle of the jet,  $\delta_j$ , calculated from

$$\delta_j = \nu_1 - \nu_j + \theta_N \quad (1)$$

The condition of constant pressure along the jet boundary is then used to determine the changes in jet boundary angle required to compress the flow and balance the pressure decrease caused by the one-dimensional flow area increase. The relation between turning angle and pressure change is given by the Prandtl-Meyer expansion relation

$$\frac{\Delta p}{p} = \frac{\gamma M_1^2}{\beta_1} (\Delta \nu) + \text{higher order terms in } \Delta \nu \quad (2)$$

which is identical (except for sign of  $\Delta \nu$ ) to the expression for a compression through an oblique shock wave, up to and including the term in  $(\Delta \nu)^2$ . It is apparent then that two jets that have the same value of the coefficient  $\gamma M_1^2/\beta_1$  could be expected to have the same pressure change-deflection angle relation within the limits of the linearization of Eq. (2). This therefore gives rise to the use of  $\delta_j$  and  $\gamma M_1^2/\beta_1$  as the jet boundary simulation parameters.

### 2.2 METHOD-OF-CHARACTERISTICS SOLUTION

The most accurate method existing for calculating the properties of an inviscid expanding jet is the method of characteristics. However, the accuracy obtained in the actual application depends on factors such

as the knowledge of the actual flow properties at the start of the calculation (the nozzle exit), the frequent assumption of neglecting the jet boundary shock, and the nonideal behavior of the gas. Also, the accuracy is limited by the computer program used because of the finite mesh size rapidly becoming larger as the solution proceeds downstream. In most applications, the effects of the viscous mixing on the jet boundary must be considered.

Application of method-of-characteristics solutions to determine the free jet boundaries have been made by several authors (Refs. 2, 5, and 7 through 12). Among these, Refs. 2, 5, and 7 included limited experimental data for sonic nozzles or low to moderately expanding jets from supersonic nozzles. Experimental determination of jet boundaries for highly underexpanded jets has been prevented by the density limitations of conventional optical instrumentation; therefore a "glow discharge" technique was used in Ref. 12. The method-of-characteristics solution was also compared in Ref. 13 with experimental data on the internal structure of jets expanding into a vacuum. In general, the above authors found the method of characteristics to reasonably predict the jet boundaries and flow properties, within its inherent limitations. A good survey of some of the exact and approximate solutions for the jet structure has been given by Adamson (Ref. 14).

The computer program used for the present calculations was developed by the Lockheed Missile and Space Corporation for use with the IBM 7090 computer. This program computes the supersonic flow properties of a gas discharging from an underexpanded nozzle into either a quiescent atmosphere or a hypersonic free stream. Ideal gas relations, oblique shock relations for the boundary shock, and the axisymmetric method of characteristics are employed. A complete description of the program is given in Ref. 15, and only the principal assumptions and the techniques used in the application of the program are given here.

Jet boundaries presented in this report were computed on an IBM 360/50 computer for the following conditions and assumptions:

1. For the case of a quiescent atmosphere only.
2. Nozzle exit flow properties were computed by the program from ideal gas, one-dimensional flow relations utilizing point source flow (spherical areas). Specific heat ratios of 1.28, 1.40, and 1.667 were used for both the nozzle and the jet flows. The value

of 1.28 used for comparison with experimental tests of CO<sub>2</sub> corresponds to excitation of one of the four modes of the molecular vibration.

3. The method-of-characteristics computation starts on the spherical nozzle exit surface; normally 40 points were used for the origin of the characteristic net.
4. Flow properties for the initial expansion around the nozzle lip are computed from Prandtl-Meyer relations. Approximately 1.5-deg increments were used for the Prandtl-Meyer expansion system.

Recently a new program has been developed (Ref. 16) which includes equilibrium reacting gas mixtures and a wider variety of flow field problems. A comparison of this program with some experimental data is given in Ref. 17. These comparisons include limited data from jets with sonic nozzles and with low exit pressure ratio supersonic nozzles. In general the comparisons were considered very good. This program (Ref. 16) is currently being adapted to the AEDC computer system.

### 2.3 JET BOUNDARY VISCOUS MIXING REGION

The velocity gradients normal to the flow direction in the interior of the jet are usually small, and therefore viscosity effects are neglected. The jet interior structure can then be calculated by the method of characteristics as described previously. However, the gradients are not negligible at the jet boundary, and effects of viscous mixing must be considered.

Ideally, the inviscid boundary can be determined and the flow properties at the inviscid boundary used to determine the corresponding mixing region flow properties. The viscid mixing solution can then be superimposed on the inviscid jet solution to define the physical jet. This procedure is probably valid if the mixing region is small compared to the jet radius and if no chemical reactions occur.

The growth of the turbulent mixing region was calculated for the conditions corresponding to the present experimental tests using the method given by Bauer in Ref. 18. The type of mixing considered is turbulent, two-dimensional, compressible, isobaric, isoenergetic, and without an initial boundary layer. It is of significance to note that for the high jet boundary Mach numbers considered in this report, the mixing region thickness and velocity distributions are almost identical for all jets. For these, the edges of the mixing regions are:  $n/r_e/l_1/r_e = 0.13$  for the outer edge and  $-0.01$  for the inner edge.

### SECTION III APPARATUS AND TEST PROCEDURE

#### 3.1 TEST HARDWARE AND PROCEDURE

The experiments reported in this report were conducted in an 18-in. test cell connected to a six-stage steam ejector. The test cell installation is shown in Fig. 1, Appendix I. Test gases were heated by a resistance-type heater and expanded through conical nozzles into the test cell. Test nozzles had throat diameters of approximately 0.1 in.

Two sets of values of the simulation parameters were selected as being representative of typical underexpanded jet plumes:

$$\delta_j = 60 \text{ deg}, \gamma M_1^2 / \beta_1 = 14$$

and

$$\delta_j = 60 \text{ deg}, \gamma M_1^2 / \beta_1 = 18$$

These values of the simulation parameters were maintained constant, and tests were conducted with pure gases in 10- and 20-deg half-angle conical nozzles. Nitrogen, CO<sub>2</sub>, and He gases were tested at a simulation parameter value of 14; N<sub>2</sub> and He were tested at a value of 18. Different values of ambient pressure and nozzle area ratio were required for each of 10 different nozzles in order to maintain the selected values of the simulation parameters.

Since each gas required a different nozzle area ratio to match the selected value of the simulation parameters, testing began with CO<sub>2</sub> (the largest nozzle area ratio). The nozzle exit was then cut off to give the required area ratios for N<sub>2</sub> and He. The configurations of the various test nozzles are shown in Fig. 2.

Possible effects of nozzle boundary layer, jet viscous mixing, gas condensation, specific heat ratio variation, and gas nonequilibrium could not be precisely evaluated beforehand; therefore, tests were conducted over a range of stagnation pressures from 100 to 400 psia; and, temperatures from 100 to 1000°F. At each test condition, cell ambient pressure was adjusted to give the required jet expansion to match the chosen values of the simulation parameters. All tests were conducted under steady-state conditions.

### 3.2 FLOW VISUALIZATION

A glow discharge technique was used to illuminate the jet plume so that it could be photographed, since the required test cell pressures were well below the sensitivity limit of conventional optical techniques. The glow discharge technique, previously used for jet plume studies in Ref. 12, utilized an electrically charged probe approximately 5 in. downstream of the nozzle exit. This electrical charge was supplied by Osram<sup>®</sup> ignition unit originally designed for ignition of 2000-w high-pressure xenon arc lamps. This unit is rated at 40 kv-RF at 18 ma.

Very small amounts of N<sub>2</sub> or CO<sub>2</sub> gas were bled into the upstream end of the test cell through a manifold ring. This technique, discussed in Ref. 12, provides a fine adjustment of the test cell pressure but was used primarily to give a color contrast between the jet and the ambient atmosphere. This is achieved by inbleeding CO<sub>2</sub> when using N<sub>2</sub> as the jet gas and vice versa. Although the color of the gas discharge varies somewhat with pressure level and gas temperature, the generally blue glow of the CO<sub>2</sub> improves the boundary contrast between the pink glow of the N<sub>2</sub>. Carbon dioxide was also used for the inbleed gas in the tests with He. Figure 3 gives an interior view of the test cell showing the electrical probe and the gas inbleed manifold installation.

The illuminated plumes were photographed with a 35-mm camera equipped with a 50-mm lens. Ektachrome<sup>®</sup> ER-ASA160-Tungsten Balance film was used, and exposure times were normally 1/30 sec. Data were obtained at several exposure settings at each test condition, with f/4 generally giving best results. Optimum exposure varied with jet stagnation temperature and pressure. No change in boundary location could be detected as a result of a change in exposure.

Typical photographs of the jet plumes are shown in Fig. 4. Also shown in the figure are the boundary points that were selected as the experimental data as well as the theoretical method-of-characteristics solutions. The original color positives were projected, and both top and bottom boundaries were measured and averaged to give the plotted data presented later in this report.

The light emitted by the excited gas has been shown to be nearly a linear function of the gas density for the pressure range of these tests (Ref. 19). For the highly expanded plumes investigated, the gas density very rapidly decreases downstream of the nozzle exit as typically shown in Fig. 5. However, downstream at the boundary shock (which lies close to the inviscid boundary) an order-of-magnitude rise in density occurs,

giving the bright band of light. The outer edge of this band was measured as being the jet boundary. Near the nozzle exit the jet boundary tends to disappear, particularly for the CO<sub>2</sub> and the N<sub>2</sub> jets. The disappearance of the boundary may be attributed to a number of effects, including the shorter viewing path through the three-dimensional jet at the smaller axial distances, glow phenomena electrode effects, and the nozzle boundary layer.

### 3.3 PRESSURE PROBE TRAVERSES

To confirm that the visible boundary did in fact closely represent the physical jet, limited pressure probe traverses were made through the CO<sub>2</sub> and N<sub>2</sub> jet boundaries. These traverses were made parallel to the jet axis and do not necessarily give the pitot pressure. The probe tip was 1/8 in. in diameter and is shown in Fig. 3. Results of these tests are shown in Fig. 6. Generally good agreement is shown between the jet boundary indicated by the pressure probe traverse and that obtained with the glow discharge technique.

## SECTION IV RESULTS AND DISCUSSION

### 4.1 THEORETICAL JET BOUNDARIES

Jet boundaries were calculated by the Latvala approximation and by the method of characteristics for values of the simulation parameters of  $\delta_j = 60$  deg and  $\gamma M_1^2/\beta_1$  equal to 10, 14, 18, and 22. Boundaries were computed corresponding to nozzle half-angles of 10 and 20 deg with jet specific heat ratios of 1.667, 1.40, and 1.28. These calculations cover a very wide range of possible operating conditions, as shown in Table I (Appendix II) and in Fig. 7.

Results of the calculations by the Latvala approximation are shown in Fig. 8, and by the method of characteristics in Fig. 9. Note that since the Latvala approximation starts after the jet expansion to ambient pressure, the calculations shown in Fig. 8 are valid for all values of the nozzle half-angle,  $\theta_N$ . These computations show the Latvala approximation to give almost exact boundary duplication for all conditions calculated, whereas the method of characteristics predicts substantial divergence between boundaries, especially at the lower values of  $\gamma M_1^2/\beta_1$ . Somewhat closer boundary duplication for

the method-of-characteristics solutions is obtained by adding the nozzle half-angle,  $\theta_N$ , as an additional parameter. Also note that the boundaries with a specific heat ratio,  $\gamma$ , of 1.667 diverge the greatest, and that for most applications good boundary simulation would be obtained for axial distances of 10 to 15 nozzle exit radii by using air ( $\gamma = 1.4$ ) to simulate a hot rocket ( $\gamma = 1.28$ ).

## 4.2 EXPERIMENTAL RESULTS

Results of experimental tests with  $\text{CO}_2$ ,  $\text{N}_2$ , and He for  $\gamma M_1^2/\beta_1 = 14$  are shown in Fig. 10, and tests with  $\text{N}_2$  and He for  $\gamma M_1^2/\beta_1 = 18$  are shown in Fig. 11. Carbon dioxide was not used in the tests with  $\gamma M_1^2/\beta_1 = 18$  because of the very low ambient pressures and the very large nozzle area ratios (Fig. 7) required. Data symbols are only shown for the portions of the boundaries for which a distinct boundary could be determined from the projected negatives and are shown as read, without any fairing or smoothing. Also shown are the theoretical boundaries as calculated by the method of characteristics. Since tolerances in machining the test nozzles will cause errors in the jet initial angle,  $\delta_j$ , the actual initial angle is shown and the theoretical boundaries recalculated if the test value deviated more than 1 deg from the desired 60 deg. The experimental data generally lie slightly outside the method-of-characteristics solutions, as would be expected for a viscous fluid. However, little effect of gas stagnation temperature or pressure is observed, indicating little effect of nozzle boundary layer, gas condensation, or changes in the boundary viscous mixing. The exception is the data for  $\text{N}_2$  at high stagnation pressures.

The boundary increase shown for the high stagnation pressure  $\text{N}_2$  is real, as previously shown by the pressure probe data in Fig. 6a, and not just an apparent change caused by the flow visualization technique. Such a change could be caused by gas condensation in the test nozzles or in the jet plume. The very large rates of gas expansion in the nozzles and in the plumes would give a substantial amount of supersaturation before condensation would occur. However, as shown in Fig. 12, even equilibrium condensation in the test nozzles is possible only for the  $\text{CO}_2$  at 300°F and condensation with the 100°F, 100-psia stagnation test conditions would occur far before condensation at the 1000°F, 500-psia conditions. The close agreement of the nitrogen boundaries at low stagnation pressure test conditions and for all conditions with  $\text{CO}_2$  shows that gas condensation in the jet plume either does not occur or has no effect on the measured jet boundaries.

An analysis was made of the experimental  $\text{N}_2$  data for possible effects of the nozzle boundary layer or changes in the jet boundary mixing region. The maximum change in the nozzle exit flow properties that can be caused

by the displacement thickness of a turbulent boundary layer will cause only a 0.5-deg increase in jet boundary initial angle,  $\delta_j$ . This change is not sufficient to cause the boundary location increase shown for the high stagnation pressures. However, an analysis of the deviation of the experimental boundaries from the method-of-characteristics solutions shows excellent agreement when the data are correlated by the Reynolds number at the nozzle exit. This correlation is shown in Fig. 13, which also includes the data with He and CO<sub>2</sub>. The Reynolds number is based on the length along the nozzle wall from the throat to the exit and the viscosity data of Ref. 20 for He and of Ref. 21 (extrapolation required for lowest temperatures) for N<sub>2</sub> and CO<sub>2</sub>. The critical Reynolds number indicated in Fig. 13 is almost identical with the values given in Ref. 22 for flat plates with comparable Mach numbers. A somewhat higher critical Reynolds number would be expected for the nozzle flow because of the favorable pressure gradient; however, the choice of the proper length for nozzle flows is uncertain. Also shown in Fig. 13 are the edges of the turbulent mixing region calculated as described in Section 2.3, which gives good agreement with the data at the higher Reynolds numbers. Although it would be attractive to attribute the smaller jet boundaries at the lower Reynolds numbers to a laminar jet boundary, Ref. 23 would indicate laminar boundary thicknesses comparable to or thicker than that for a turbulent boundary. However the velocity profile assumed in Ref. 23 may not be valid at the very high Mach numbers of the experimental jet boundaries. It is significant that the inviscid method of characteristics does give a good representation of the physical jet boundary, although insufficient knowledge of the viscous mixing process and the factors affecting it may not always allow an absolute correction for the mixing.

In general, excellent agreement is obtained between the inviscid method-of-characteristics solutions and the experimental data. It is therefore believed that the validity of this program with the inputs and techniques used has been confirmed and that a comparison of simulation parameters can now be made using the method-of-characteristics calculations for the jet boundaries rather than requiring experimental measurements.

#### 4.3 ANALYSIS OF OTHER SIMULATION PARAMETERS

Although the proposed simulation parameters  $\delta_j$  and  $\gamma M_1^2 / \beta_1$  do provide good simulation for most cases of practical interest, they do not appear to be the completely general tool that one desires. Therefore with the method-of-characteristics program confirmed as a method of calculating the physical jet boundary, a limited analysis of

some of the other proposed simulation parameters was made. Among the parameters investigated were:

1.  $\gamma M_j^2 / \beta_j$  and  $\delta_j$
2.  $\gamma M_j^2 / \beta_j$  and  $p_j / p_\infty$  (Ref. 3)
3.  $\gamma M_j^2 / \beta_j$ ,  $p_j / p_\infty$  and  $\delta_j$  (Ref. 1)

Results of this limited analysis are shown in Fig. 14. Of the sets of parameters studied none except the third set gave results as good as the  $\gamma M_1^2 / \beta_1$  and  $\delta_j$  suggested in Ref. 4. However it should be noted that the third set requires the matching of three quantities rather than two, and is therefore a more restricted simulation.

The use of the third set of simulation parameters shown above implicitly specifies a value of  $\theta_N$ . The required value of  $\theta_N$  is therefore shown in Fig. 14c which presents a set of boundaries calculated for the given set of simulation parameters.

#### 4.4 SIMULATION PARAMETERS $\delta_j$ AND $M_1/\gamma$

A rapid analysis of any other parameter in combination with  $\delta_j$  can be made from the existing method-of-characteristics solutions for  $\delta_j = 60$  deg. This is done by observing the variation of the jet boundary radial locations at a fixed axial station as compared to changes of the parameter under study. Ideally then, boundary locations for all calculations should give a smooth progression for the changes of the selected parameter. A summary of the calculated boundaries from which the analysis can be made is shown in Fig. 15.

The analysis described above was made on several parameters involving combinations of  $M_1$  and  $\gamma$ . This analysis shows excellent correlation of the boundary location when  $\delta_j$  and  $M_1/\gamma$  are used as the simulation parameters. A slight improvement in correlation can be gained by also duplicating  $\theta_N$  as a third parameter. Sample results of this analysis are shown in Fig. 16. Excellent correlation of the boundary locations is shown.

Based on the preceding analysis, additional boundary calculations were made by the method of characteristics to determine the range of applicability of the parameters  $\delta_j$  and  $M_1/\gamma$ . Calculations were made for the following conditions:

1. Jet boundary initial angles,  $\delta_j$ , of 45, 60, and 75 deg.
2. Simulation parameter  $M_1/\gamma$  values of 5, 7, 10, and 13.
3. Specific heat ratio of 1.28 and 1.667.
4. Nozzle half-angle,  $\theta_N$ , of 10 and 20 deg.

The very wide range of conditions covered by these calculations is shown in Table II and in Fig. 17.

Results of the calculations are shown in Figs. 18, 19, and 20. Excellent agreement between the boundaries is obtained over the very wide range of conditions investigated. Some improvement is obtained by including the nozzle half-angle,  $\theta_N$ , as a third simulation parameter. Also note that the boundaries are presented for two extreme cases of the specific heat ratio, 1.28 and 1.667 only; for most practical applications using diatomic gases, the boundaries would show even better agreement.

#### 4.5 A RAPID METHOD FOR ESTIMATING THE INVISCID BOUNDARY LOCATION

The close correlation of jet boundaries with the simulation parameters  $\delta_j$ ,  $M_1/\gamma$ , and  $\theta_N$  gives rise to a very simple method of rapidly estimating the inviscid boundary location. Boundary locations at fixed axial stations are shown in Figs. 21 and 22 as a function of the jet initial angle,  $\delta_j$ , and the parameter  $M_1/\gamma$  for nozzle half-angles of 10 and 20 deg. The estimating procedure is as follows:

1. From Eq. (1) the initial angle of the jet,  $\delta_j$ , is calculated. This establishes the slope of the boundary at the nozzle exit.
2. Calculate  $M_1/\gamma$  from the known stagnation pressure, ambient pressure, and specific heat ratio.
3. The boundary location  $r/r_e$  can then be located at  $x/r_e = 5, 10, 18$ , and 25 from Fig. 21 for  $\theta_N = 10$  deg or Fig. 22 for  $\theta_N = 20$  deg. This provides up to five known points plus the initial angle,  $\delta_j$ , and is normally enough for an accurate boundary. If desired, additional figures similar to Figs. 21 and 22 can be constructed at any  $x/r_e$  from Figs. 18, 19, and 20.
4. The small correction for other values of  $\theta_N$  can be made by a comparison of the boundaries at 10 and 20 deg.

## SECTION V CONCLUDING REMARKS

The theoretical and experimental investigation of jet boundary simulation parameters for underexpanded jets in a quiescent atmosphere indicate the following conclusions:

1. Experimental jet boundaries are in excellent agreement with the inviscid jet boundaries as determined by the method of characteristics.
2. Pindzola's parameters ( $\delta_j$  and  $\gamma M_1^2/\beta_1$ ) give good boundary simulation for 10 to 15 nozzle exit radii for most applications using air ( $\gamma = 1.4$ ) to simulate a hot rocket ( $\gamma = 1.28$ ).
3. However, the use of  $\delta_j$  and  $M_1/\gamma$  provides excellent boundary duplication over a wider range of conditions and to much larger axial distances. In addition, a slight improvement in the correlation can be gained by also duplicating  $\theta_N$  as a third parameter.
4. A procedure developed from the method-of-characteristics solutions gives a rapid, simple method for estimating the jet boundary shape for jets with boundary initial angles from 45 to 75 deg.

13. ABSTRACT An experimental and theoretical investigation was conducted to determine the degree of jet boundary simulation obtainable for under-expanded jets exhausting into a quiescent atmosphere. Tests were conducted with nitrogen, carbon dioxide, and helium gases, and theoretical boundaries were obtained by a method-of-characteristics solution. It was determined that the method-of-characteristics solution accurately represents the experimental jet boundaries and that the matching of the parameters $\delta_j$ and $M_1/\gamma$ gives good boundary simulation for a wide range of jet conditions. Also a rapid, simple method for estimating jet boundary shape is developed from the method-of-characteristics results.
